Advancements in Low-Latency Machine Learning and Sensory-Motor Integration for Gamified Virtual Reality Knee Rehabilitation

The integration of immersive technology into orthopedic rehabilitation has transitioned from a niche experimental field into a robust area of medical engineering. The primary objective of this report is to delineate the technical, clinical, and human-factor requirements for a high-performance, real-time motion tracking system specifically designed for "Architect," a gamified knee rehabilitation prototype. Central to this inquiry is the optimization of the temporal relationship between a patient's physical exertion and the resulting virtual feedback. In virtual reality (VR), the sensory-motor loop is highly sensitive to latency; any delay between proprioceptive input and visual representation can degrade motor learning, break the sense of presence, and induce simulator sickness.[1] This analysis synthesizes contemporary literature (2020–2026) to provide a roadmap for developing a system that achieves sub-30ms end-to-end latency using markerless machine learning (ML) frameworks and consumer-grade hardware.

Technical Foundations of Real-Time Markerless Pose Estimation

The technical viability of the "Architect" concept rests upon the ability to extract skeletal data from a standard RGB video stream with minimal computational overhead. Traditional methods for motion capture, while precise, require expensive multi-camera arrays and reflective markers, making them unsuitable for home-based or flexible clinic-based rehabilitation.[3] Markerless pose estimation, driven by deep learning, offers a transformative alternative.

Evolutionary Paradigms in Machine Learning Pose Architectures

Current research identifies two primary paradigms for human pose estimation: bottom-up and top-down approaches. Top-down methods, such as those utilized in the MMPose ecosystem and RTMPose models, typically achieve higher accuracy by first employing an object detector to locate the person within a frame and then running a pose estimation model on the resulting bounding box.[4] This architecture allows the system to focus its computational power on relevant pixels, improving the signal-to-noise ratio in joint detection.

The RTMPose series, based on the CSPNeXt backbone, represents the current state-of-the-art for real-time applications. On high-end GPUs like the NVIDIA RTX 4090,

RTMPose-m achieves an end-to-end latency of 7ms with an Average Precision (AP) of 74.3 on the COCO dataset.[4] For mobile or edge deployments, RTMPose-s maintains high performance on chipsets like the Snapdragon 865, achieving 70+ frames per second (FPS), which corresponds to a frame-to-frame delay of approximately 14.2ms.[6]

Model Variant	Backbone	Hardware	Latency (ms)	Throughput (FPS)	Accuracy (AP)
RTMPose-m	CSPNeXt-m	RTX 4090	7	142.8	74.3
RTMPose-l	CSPNeXt-l	RTX 4090	10	100.0	75.8
RTMPose-m	CSPNeXt-m	Intel i7-11700	~11	90.0	75.8
RTMPose-s	CSPNeXt-s	SD 865 (Mobile)	~14	70.0	72.2
TinyPose	HRNet-Lite	Mobile CPU	<20	50.0	60.9

The significance of these latency figures for the "Architect" game cannot be overstated. When a patient performs a single-leg balance task, the stability of the virtual environment is contingent upon the visual representation of their center of mass (CoM) being updated faster than the brain's internal prediction models can detect a discrepancy.

MediaPipe and the BlazePose Pipeline

Alternatively, the Google MediaPipe framework offers a highly optimized "BlazePose" model designed specifically for mobile and web platforms. This system utilizes a two-step detector-tracker pipeline.[8] In this configuration, the person detector is only run on the initial frame or when tracking is lost. For all subsequent frames, the system uses the predicted landmarks from the previous frame to define the region of interest for the current frame.[8] This temporal consistency significantly reduces the GFLOPs (Giga Floating Point Operations per Second) required for each frame.

Despite its efficiency, MediaPipe data often exhibits high-frequency noise or "jitter," which can be detrimental in a clinical setting where joint angle precision is required for range of motion (ROM) assessment.[3] To mitigate this, research suggests the implementation of 10th-order Butterworth low-pass filtering or the 1-Euro filter.[7] The 1-Euro filter is particularly relevant for interactive systems as it uses a speed-based adaptation to minimize lag during fast

movements while maintaining high smoothness during slow, static poses.[7]

Hardware Constraints and the Latency Bottleneck

The request to utilize a GoPro Hero 4 as the primary sensor introduces a significant technical bottleneck. Unlike dedicated webcams or industrial machine vision cameras, action cameras like the GoPro Hero 4 are optimized for high-bitrate recording rather than low-latency live streaming. Technical documentation and user reports indicate that the minimum "glass-to-glass" latency (the time from photons hitting the sensor to pixels appearing on a screen) for the GoPro Hero 4 is approximately 210ms over USB or Wi-Fi.[10]

Connection Strategy	Protocol	Resolution	Estimated Latency	Clinical Feasibility
GoPro 4 USB	NCM/MPEG-TS	1080p	210ms - 500ms	Non-viable for VR
GoPro 4 HDMI	Micro-HDMI Out	4K/2.7K	80ms - 150ms	Borderline/Unstable
Standard USB 3.0	UVC	720p/60	<30ms	Highly Viable
Logitech Brio	UVC	4K/30	<50ms	Viable

For a VR loop aiming for < 30 ms, a 210ms delay is catastrophic. Such latency levels are well above the 63ms threshold where simulator sickness is significantly induced.[1] To achieve the goals of the "Architect" game, a move toward high-frame-rate USB webcams (capable of 60 FPS or higher) is recommended, as high resolution is often downsampled by the ML models (typically to 256x256) anyway.[11]

Clinical Pillars of Knee Rehabilitation and Proprioceptive Training

The "Architect" game focuses on single-leg balance (SLB) and proprioceptive training, which are essential for recovery post-Total Knee Arthroplasty (TKA) or ACL reconstruction. Proprioception is defined as the afferent information arising from internal mechanoreceptors, which is integrated by the central nervous system (CNS) to maintain postural stability.[12]

Mechanisms of Proprioceptive Recovery

Surgical procedures often disrupt the sensory feedback loops in the knee joint. For instance, TKA involves the excision of the anterior and/or posterior cruciate ligaments, which are dense with mechanoreceptors. Consequently, patients often experience a "de-afferented" state where the knee "doesn't feel right".[14] Proprioceptive training interventions aim to restore this function through active movement and somatosensory stimulation.[12]

A pivotal prospective randomized study of 80 TKA patients demonstrated that proprioception-based rehabilitation—including tasks like tandem walking, figure-of-8 walks, and single-leg standing on foam pads—yielded significantly better functional outcomes than routine strength training.[15]

Clinical Test	PE Group (6 Months)	RE Group (6 Months)	Improvement Delta
6-Minute Walk	649.60 m	448.32 m	+201.28 m
30s Chair Stand	21.07 reps	18.63 reps	+2.44 reps
40m Fast Walk	0.308 min	0.557 min	-0.249 min
TUG Test	0.204 min	0.377 min	-0.173 min

These results suggest that the "Architect" game should prioritize balance and coordination over raw strength. By requiring the patient to build structures in a virtual space while standing on one leg, the game facilitates "re-calibration" of the joint position sense.[15]

Virtual Reality vs. Mirror Therapy in Motor Learning

The "Architect" game seeks to replace traditional mirror feedback with an immersive VR avatar. In conventional therapy, mirror feedback is used to provide a visual illusion of the affected limb moving correctly.[16] However, this method has limitations: patients often adopt an asymmetrical posture to view their reflection, which can interfere with the very balance they are trying to improve.[16]

VR rehabilitation environments, such as the Computer Assisted Rehabilitation Environment (CAREN), solve this by projecting a gender-neutral avatar into the user's field of view.[17] This provides an objective representation of movement without the psychological baggage associated with body dysmorphia or the physical constraints of looking in a mirror.[17] Research indicates that VR biofeedback is particularly effective in correcting sagittal plane

biomechanics, with 77% of patients showing joint angle improvements during squats.[17]

Human Factors and the Latency-Presence-Sickness Tradeoff

The psychological success of a VR medical intervention depends on the balance between immersion and comfort. This balance is dictated by the "Latency-Presence-Sickness" triad.

Thresholds of Perception and Dysfunction

Latency in VR is defined as the "motion-to-photon" delay. High end-to-end latency causes a mismatch between the vestibular system (which senses actual head movement) and the visual system (which sees the delayed virtual movement). This sensory conflict is the primary driver of VRISE (Virtual Reality Induced Symptoms and Effects), commonly known as cybersickness.[18]

Current research has identified specific thresholds where latency begins to degrade the experience:

1. **16ms–20ms**: The perceptual threshold where users can first distinguish a delay in high-speed gaming scenarios.[2]
2. **63ms**: The point at which significant cybersickness symptoms begin to manifest on the Simulator Sickness Questionnaire (SSQ).[1]
3. **75ms**: The limit where motor performance and simultaneity perception (the feeling that the action and feedback happen at the same time) are significantly impaired.[19]
4. **125ms**: The point where the "sense of agency" (the feeling that one is the cause of an action) and "body ownership" (the feeling that the virtual limb is one's own) begin to break down.[1]

For the "Architect" game, which involves delicate single-leg balance, the target latency must be < 30 ms. This is because postural stability is even more sensitive to delay than simple cognitive tasks. Studies using Wii Balance Boards have found that balance begins to decrease with added latencies as small as 1ms in highly sensitive individuals.[1]

Frame Rate and Perceptual Mismatch

Beyond raw latency, the frame rate (measured in FPS) determines the "frame time," or the interval between visual updates. The equation for frame time is:

$$T = \frac{1}{f} \times 1000$$

where T is time in ms and f is frequency in Hz.

A jump from 60 FPS (16.67ms frame time) to 72 FPS (13.89ms) reduces the delay by 2.78ms. While this appears minor, industry data shows it is a critical "comfort threshold" for VR.[20] At 60 FPS, 30–80% of users experience motion sickness in active scenarios, whereas at 72 FPS, accessibility rates rise to over 90%.[20] For medical applications, targeting 90 FPS or 120 FPS is ideal to ensure that the patient's focus remains on the rehabilitation task rather than their nausea.[21]

Attentional Focus and the "Architect" Game Concept

The "Architect" game concept utilizes an **External Focus of Attention (EFA)**, which is a key motor learning principle. EFA involves directing the learner's attention to the effect of their movement on the environment (e.g., "keep the building steady") rather than the movement of their own body (e.g., "squeeze your quad").[22]

The Constrained Action Hypothesis (CAH)

The Constrained Action Hypothesis posits that an internal focus of attention (IFA) causes the individual to consciously monitor their movements, which interferes with the automatic, reflexive motor control processes of the subcortical brain regions.[23] Conversely, an EFA allows the motor system to self-organize and function more efficiently.

Focus Condition	Instruction Example	Neural Mechanism	Functional Result
Internal (IFA)	"Keep your knee over your foot."	Top-down cortical control.	Higher muscle activity; less coordination.
External (EFA)	"Point your knee toward the cone."	Subcortical automaticity.	Lower muscle activity; higher efficiency.
Gamified (EFA)	"Keep the architect's tower upright."	Implicit learning.	Max balance stability; high retention.

Research using EEG has shown that EFA reduces cognitive effort during balance tasks, characterized by decreased alpha and increased beta power in the frontal regions.[25] By gamifying the balance task (the "Architect" mechanic), the patient is naturally drawn into an

EFA, which promotes better retention and transfer of the learned movement to real-world scenarios like walking on uneven surfaces.[23]

Systematic Literature Search Results

The following ten papers represent high-impact research (2020–2026) that informs the technical and clinical architecture of the proposed system.

1. RTMPose: Real-Time Multi-Person Pose Estimation Based on MMPose

Authors: Jiang, T., Lu, P., Zhang, L., Ma, N., Han, R., Lyu, C., Li, Y., & Chen, K. (2023).

- **Technical Specs**: MMPose framework; CSPNeXt backbone. Achieves **7ms - 10ms latency** on NVIDIA RTX 4090 and ~14ms on mobile devices.
- **Methodology**: Extensive validation across COCO and CrowdPose datasets with inference speed benchmarks on CPU, GPU, and Mobile (SD 865).
- **Key Finding**: This paper provides the state-of-the-art inference engine for the "Architect" game, ensuring that the tracking delay remains well within the 30ms requirement for responsive embodiment.

2. MediaPipe Pose: A Low-Computational-Resource Pose Estimation Model

Authors: Lugaresi, C., et al. (2020 Update).

- **Technical Specs**: MediaPipe BlazePose; utilizes standard 720p webcams; measured latency **<50ms** on consumer laptops.
- **Methodology**: System validation using a detector-tracker pipeline to reduce per-frame processing costs.
- **Key Finding**: It offers a highly accessible fallback for patients with low-spec hardware, provided that 10th-order Butterworth filtering is applied to the output landmarks to remove jitter.

3. Effects of Proprioception-Based Rehabilitation After Total Knee Arthroplasty

Authors: Jogi, et al. (2024).

- **Technical Specs**: Prospective randomized study comparing PE (Proprioceptive Exercise) vs RE (Routine Exercise).
- **Methodology**: Sample size $N = 80$ TKA patients; 6-month longitudinal follow-up with OARSI performance tests.
- **Key Finding**: Confirms that balance-focused training is significantly more effective than

pure strength training, validating the "Architect" game's clinical focus on proprioception.

4. Virtual Reality to Provide Visual Feedback to Correct Lower Extremity Biomechanics

Authors: Klausing, M. R., & Scott, K. (2025).

- **Technical Specs**: CAREN system; uses 3D motion capture and a 180-degree screen to project gender-neutral avatars.
- **Methodology**: Retrospective case series (Pilot study) focused on Knee Dominant Squat (KDS) and Dynamic Q-Angle (DQA) correction.
- **Key Finding**: This study provides the biomechanical targets (KDS and DQA) that the "Architect" game should track to ensure the patient is performing knee exercises safely.

5. Latency Thresholds for Cybersickness and Performance in Immersive VR

Authors: Stauffert, et al. (2021).

- **Technical Specs**: Immersive VR environment using artificial delay injection from 0ms to 200ms.
- **Methodology**: User study (N=68) measuring Simulator Sickness (SSQ) and motor performance.
- **Key Finding**: Establishes the **63ms sickness threshold** and 75ms performance decay limit, which are the primary technical guardrails for any VR rehab system.

6. Virtual Reality Reflection Therapy (VRRT) for Lower Limb Rehabilitation

Authors: Kim, J. H., et al. (2020).

- **Technical Specs**: VRRT system using camcorder input (webcam type) and screen-based visual illusion.
- **Methodology**: Randomized controlled trial ($N = 25$); measured Berg Balance Scale (BBS) and Timed Up and Go (TUG).
- **Key Finding**: Demonstrates that viewing a virtual representation of the limb is more beneficial than traditional mirror therapy, directly supporting the "Architect" game's use of avatars.

7. External Focus of Attention Influences Cortical Activity in Single Limb Balance

Authors: Sherman, D. A., et al. (2021).

- **Technical Specs**: EEG monitoring (Alpha/Beta bands); single-leg balance tasks on firm

and foam surfaces.
- **Methodology**: Comparative study of 32 healthy adults under IFA and EFA instructional conditions.
- **Key Finding**: Proves that EFA (the core mechanic of "Architect") promotes neural efficiency and automaticity, whereas focusing on the knee joint itself (IFA) hinders motor learning.

8. The 72 FPS Standard: Reducing Nausea in Free-Roam Virtual Reality

Authors: Battle Start Engineering Technical Report (2024/2025).

- **Technical Specs**: Frame time analysis; comparing 60 Hz vs 72 Hz refresh rates.
- **Methodology**: Analysis of 1,000+ user sessions in free-roam movement scenarios.
- **Key Finding**: Identifies that a 72 FPS target significantly reduces the brain's perceptual mismatch, ensuring that the "Architect" game is comfortable for elderly or post-operative patients.

9. Impact of Latency on Mirror-Image Simultaneity and Motor Performance

Authors: Waltemate, T., et al. (2016/Updated context 2023).

- **Technical Specs**: CAVE environment; full-body avatar system; latency range 45ms to 350ms.
- **Methodology**: Psychophysical procedures measuring sense of agency and body ownership.
- **Key Finding**: Shows that "body ownership" of a virtual avatar breaks down if tracking latency exceeds 125ms, making the GoPro 4 (with 210ms lag) entirely unsuitable for creating a sense of embodiment.

10. ExerCam: A Webcam-Based Telerehabilitation System for Accessible Physiotherapy

Authors: MDPI Applied Sciences (2021/2022).

- **Technical Specs**: Simple RGB webcam; OpenPose and WrnchAI libraries; real-time virtual skeleton overlay.
- **Methodology**: Feasibility study for middle-class home environments using consumer hardware.
- **Key Finding**: Validates that low-cost webcams are clinically viable for remote tracking, reinforcing the need to pivot away from high-latency action cameras for the "Architect" project.

Integrated Summary and Strategic Recommendations

The development of the "Architect" game requires a strict adherence to a < 30 ms latency budget to be clinically effective and user-friendly. The integration of RTMPose as the inference engine, combined with a 60 FPS USB 3.0 webcam, provides the most robust path forward. This configuration overcomes the 210ms "technical bottleneck" of legacy action cameras like the GoPro Hero 4 and provides skeletal data within the 7ms–14ms range.[4]

From a clinical perspective, the game's mechanic of shifting the patient's focus to an external objective ("building the architecture") is scientifically backed by the Constrained Action Hypothesis.[23] This approach not only improves the immediate stability of the patient during single-leg balance exercises but also promotes the neuroplastic changes necessary for long-term recovery post-TKA.[15]

To ensure patient safety and comfort, the software architecture must target a stable 72 FPS or 90 FPS refresh rate. This minimizes the sensory conflict between the vestibular and visual systems, keeping the SSQ scores low and the patient's motivation high. Furthermore, the use of real-time biofeedback metrics—specifically the Knee Dominant Squat (KDS) depth and the Dynamic Q-Angle (DQA)—will allow the system to provide corrective alerts if the patient moves into a valgus-prone position, effectively acting as a digital "physiotherapist" within the VR environment.[17]
